I. INTRODUCTION

A Field Programmable Gate Array (FPGA) is an interconnected circuit that can be customized for specific applications. You can customize it using the coding language Verilog. In this lab, we will build a simple TSC Trigger Surround Cache using an ADC and a ring buffer memory device. ADC records an input analog signal and converts it to a digital signal. A ring buffer is a type of storage method where you have a fixed size storage, and you have two pointers - one pointer which is the head and one pointer which is the tail. The head points to the value you are going to read from, while the tail points to the value you are going to write to. The TSC must be able to communication with other devices using transfer protocols.

II. DESIGN AND IMPLEMENTATION

A. Hardware and Software

This was run on a MacBook Pro computer using Iverilog. Additionally, gtkwave was used to monitor the wires.

B. TSC design overview

The TSC (Trigger Surround Cache) has a 3 bit state register, a 32-bit timer, a 32-bit TRIGTM, and an internal ring buffer. It is connected to the ADC (Analog-to-Digital Converter) via a request (REQ), ready (RDY), and data (DAT) lines. Additionally, the TSC can communicate with other devices using triggered (TRD), Send Buffer (SBF), serial data (SD), and completed data (CD) registers and wires.

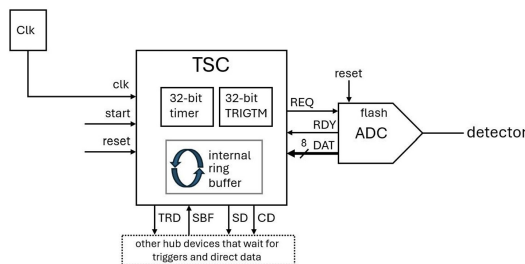

Fig. 1: Block diagram of the TSC

There is also an accompanying TSC_tb test bench which is used to initiate and test the TSC module.

C. CLock (clk)

A 250 MHz clock signal is set up on clk wire in the TS_tb test bench.

1) *State register*: The state register is a 3-bit register that has the following states:

- 000 Stop : State when the machine is powered on and has not been reset yet.
- 001 ready : State that is entered on the reset pin rising edge and it waits for the start pin rising edge.
- 010 Running : State that is entered from ready or Idle state once the start pin rising edge is pulled high. It increments the timer and writes adc values to the ring buffer.
- 011 Triggered : State entered when the value read from the ADC is greater than the predetermined trigger value (TRIGVL). It captures the next 16 values.
- 100 IDLE : This state is entered when a trigger event has occurred and the TSC is waiting for the start pin or SPF pins rising edge.
- 101 SENDING : This state is entered from the IDLE state when the SFB goes high. It indicates that data is being sent on the SD line.

2) *Timer*: The timer is incremented on the rising edge of the clock. When a trigger event occurs the timer is saved in the TRIGTM register which is outputted to the test bench. The timer is reset if a transition into a running state occurs. To calculate the time stored in the TRIGTM register the timer is multiplied by the clock period (4 ps).

3) *Ring Buffer*: The ring buffer is used to store the values read by the ADC. It is made up of 32 8-bit registers stored in an array called ring_buffer. The tail pointer is named write_ptr and is initially set to 5'b11111. and the head pointer is named read_ptr and is initially set to 5'b00000. The 5-bit format for the head and tail index is used to induce rollover at value 32 (32 just becomes 0). To add a new value to the ring buffer the write_ptr is incremented and then the value is stored in the ring buffer at the write_ptr index then read_ptr is incremented. To read a value from the ring buffer the value at the read_ptr index is read and the read_ptr is incremented. This process is repeated until the read_ptr = write_ptr. Indicates that all the values have been read.

4) *How the TSC interfaces with the ADC*: The ADC is initialized in the TSC module. This creates the adc_request, adc_ready, and DAT wires. The adc_request line is to the main reset line this means that the ADC is reset when the TSC module pulls the reset pin high. Once the ADC is reset the adc_ready line is pulled high to indicate that the ADC is ready to send data. When the TSC module detects the

adc_ready line is high and the TSC is in the running state. The TSC will pull the adc_request line high on the posedge of the clk line for 1 ps to request data from the ADC. This can be seen in the two code section below.

Listing 1: Code for storing data and moving pointers i the posedge adc_ready

```
always @(posedge adc_ready) begin
    if (adc_request) begin
        #1 //delay so the pulse doesn't disappear on the echo. TO BE REMOVED

        //manage trigger_value
        //... the trigger code is here

        //store data and move pointers around
        ring_buffer[++write_ptr] = adc_data;
        read_ptr++;

        adc_request = 0; //pull request down
    end
end
```

Listing 2: Code for requesting data from the ADC on posedge of the clock when in RUNNING state

```
'RUNNING: begin
    timer++;
    if (~ adc_request)
        adc_request = 1; //request new adc value (handled with posedge adc_ready)
end
```

III. TESTING AND VALIDATION

IV. CONCLUSION

This report shows that for multiplying small matrix sizes and counts, single-threaded matrix multiplication is faster, however, when the matrix sizes and counts are large enough, parallelized matrix multiplication becomes faster due to its overhead becoming negligible relative to its computation time.

The overheads for the parallel matrix multiplication program are the OpenCL setup overhead and kernel startup overhead, with the former being constant and the latter increasing linearly with matrix count.

Lastly, there is an unexplained decrease in speed up for small matrix sizes and matrix counts over 60 which is theorised to be caused by the matrix arrays allocation and transfer between the heap, stack and cache, however this hypothesis still requires further testing to confirm.
